SUMMARY

Purpose: To evaluate anatomical, functional and clinical efficacy of the pattern scanning laser (PASCAL®) photocoagulation in patients with diabetic retinopathy.

Methods: The cohort included 91 eyes in 50 patients (average age 63 years, 24 men and 26 women) treated at the Clinic of Ophthalmology, Faculty Hospital Ostrava, from 2008 to 2013. All eyes showed the signs of diabetic retinopathy (20.9% of eyes – very severe non-proliferative diabetic retinopathy (NPDR), 79.1% of eyes - proliferative diabetic retinopathy (PDR)). All the eyes were „treatment naive". The average duration of diabetes was 18 years, average baseline HbA1c value was 8.2 %. Panretinal photocoagulation was performed with by the means of PASCAL photocoagulator – with patterns and short duration pulses. Best corrected visual acuity (BCVA), central retinal thickness (CRT), fundus photography, biomicroscopy and complications were evaluated during the minimum of 12 months follow-up period. Statistical analysis using Shapiro-Wilk a Friedman tests with p value less than 0.05 was done.

Results: Mean baseline BCVA was 0.13 logMAR. Values 0.12, 0.15 and 0.19 logMAR were observed in the follow-up intervals at the 4th, 6th and 12th month. At the 6th month visit all 91 eyes (100 %) were stabilized, and at the 12th month visit in 5 eyes (5.5 %) progression of the disease was observed. No complications were observed during the first 12 months follow up.

Conclusion. Laser photocoagulation of the retina with the use of short pulse durations and patterns in patients with DR is an effective and safe method of treatment.

Key words: diabetic retinopathy, laser photocoagulation, patterns, low time of impulse, Pascal

INTRODUCTION

Laser systems are used in ophthalmology, in both the diagnosis and in the therapy of pathologies of the anterior and posterior segment of the eye. Laser photocoagulation (LPC) of the retina ranks among the traditional techniques of treatment that became standard in ophthalmology in the middle of the 20th century. In LPC the aim is to achieve the destruction of tissue which is significant in a range of vascular pathologies of the retina – diabetic retinopathy (DR), (8, 19), diabetic macular edema (DME), central or branch retinal vein occlusion (CRVO, BRVO), ocular ischemic syndrome, neovascular glaucoma and others. To date the standard technique for the performance of LPC in the case of DR is considered to be the protocol from the Diabetic Retinopathy Study (DRS) and Early Treatment Diabetic Retinopathy Study (ETDRS). This protocol is based on the technical prerequisites of the available laser systems, which produced individual impulses with a duration of 0.1-4 s, and its effectiveness was supported by therapeutic results and especially by the above-stated randomised studies (5, 6). In the past decade new technologies have been introduced into industry and medicine, which have led to the development of a new generation of laser systems. These utilise more precise and sophisticated crystals for focusing the beam itself. Upon simple stepping on the pedal, dozens of impulses with a duration of 20 ms and less are sent within tenths of a second. At the same time, with the aid of an electro-magnetic field, a mirror is rotated, progressively altering the position of the beam, so that the impulses are focused in "patterns". The individual traces are more homogeneous and the changes of tissues are concentrated in the outer retinal layers (RPE, outer and inner segments of photoreceptors, external nuclear layer), whilst preserving the inner retinal layers (1, 7, 16). Upon threshold photocoagulation of the retina (i.e. upon visible laser trace), in which we wish to attain an effect comparable with classic photocoagulation, the optimal impulse time appears to be 20 ms. In this a higher output is used in comparison with conventional lasers, but the tissues are exposed overall to a lower energy burden. In shorter times there is a risk of rupture of the RPE (7).

The first commercially available laser of this class was the PASCAL laser (pattern scanning laser) (1).

The aim of the submitted study is to present our experience with the performance of laser photocoagulation of the retina with the aid of a laser system, using patterns and low impulse times in patients with diabetic retinopathy (DR).

METHOD

In the period from 1 June 2008 to 30 June 2013, we selected a cohort of 91 eyes of 50 patients treated at the Department of Ophthalmology at the University Hospital Ostrava. All had very advanced non-proliferative diabetic retinopathy (NPDR) or proliferative diabetic retinopathy (PDR), and at the same time there was no presence of clinically significant DME (CSME) demonstrated by biomicroscopic examination of the fundus, colour photography of the fundus and fluorescence angiography.

For all patients an anamnesis was taken, best corrected visual acuity (BCVA) was determined for distance vision on Precision Vision optotypes with notation for testing at 4 metres – ETDRS chart 1.2 R + Illuminator Cabinet Mod. 2425E (Precision Vision, First Street, La Salle, IL, USA), and the result was converted according to the conversion table into a logarithm of minimal angle of resolution (logMAR) within the range of 0.00-1.00. At the same time spectral OCT of the macula was performed on OCT Spectralis (Heidelberg Engineering, Inc., Carlsbad, California, USA). Complete panretinal photocoagulation (PRP) of the retina was performed on all patients, using patterns and times of impulses of 20 ms with the aid of a Pascal Photocoagulator (Topcon Medical Laser Systems, Inc., Santa Clara, CA, USA). First of all the output necessary for the creation of one trace was titrated, the time of an individual impulse was 20 ms, the size of the trace 400 μm and the output was progressively increased until a laser trace of grey colour was attained. A pattern was then selected, as a rule 3 x 3, 4 x 4 or 5 x 5. The complete treatment was performed in one or two episodes/sessions. A follow-up examination was conducted 4 months after the initial examination, then 6 months from the initial examination and subsequently at six months intervals until 48 months after the initial examination. At the individual intervals the parameters displayed in table 1 were observed and evaluated. The proportions of patients were also evaluated according to changes of BCVA (improvement by more than 3 rows, improvement within the range of 0.01-3 rows, deterioration within the range of 0-3 rows and deterioration by more than 3 rows according to ETDRS optotypes). In addition, the frequency of complications was analysed. The aim was also to demonstrate the clinical effect of laser photocoagulation of the retina with the aid of the innovative laser PASCAL, which was evaluated as fulfilment of the purpose (stabilisation of the clinical finding) at subsequent follow-up examinations in comparison with the initial examination.

Stabilisation (S) was taken as constituting a stable finding within the periphery of the retina, or an improvement thereof. A condition was evaluated as progression (P) in the case of occurrence of new vitreous or preretinal haemorrhage, the occurrence of new or progression of existing neovascularisations, the advancement of retinal detachment or in the absence of regression of existing haemorrhage. From this group we further detached the subgroup "failure of treatment" (F), when even further therapeutic intervention did not lead to stabilisation of the pathology and it was no longer possible to influence the condition therapeutically.

Using the method of descriptive statistics, we compiled a description of the variables. In addition, in the case of linked variables, a Shapiro-Wilk normality test was conducted. In order to determine the significance of changes during the observation period in linked variables, depending on their normality a dispersion analyses was used for repeated measurements, or a Friedman test. All the statistical tests were conducted as bilateral on a level of significance of 0.05. The statistical analysis was conducted with the aid of the software IBM SPSS Statistics version 22.

RESULTS

The general characteristics of the cohort are displayed in table 2. In 41 eyes a complete treatment was performed during one session, in 50 patients during 2 sessions, the mean number of applied points was 2008 (range 1600-3700, median 2000, standard deviation (SD) 485).

Best corrected visual acuity

Initial BCVA was 0.13 logMAR, at subsequent follow-up examinations 0.12, 0.15 and 0.16 logMAR. The development of BCVA graphically, including the median and the 1st and 3rd quartile, is illustrated graphically in fig. 1 and 2. Table 3 presents an independent evaluation of the distribution of patients with an improvement within the range of 0.01-3 rows, a deterioration within the range of 0-3 rows and a deterioration by more than 3 rows of ETDRS optotypes 12 months after the beginning of observation. No improvement by more than 3 rows was recorded in any of our patients.

Central retinal thickness

The initial mean CRT was 259 μm, at subsequent follow-up examinations in the 4th month 259 μm, in the 6th

Table 1 Evaluated parameters and time intervals of follow-up examinations (M – month)

	0	4M	6M	12M	18M	24M	30M	36M	42M	48M

OCT	x	x	x	x						
FA	x									
Fundus photography	x	x	x	x		x		x		x
Biomicroscopy	x	x	x	x	x	x	x	x	x	x

BCVA – best corrected visual acuity; OCT – optical coherence tomography; FA – fluorescence angiography; M – month

month 260 μm and in the 12th month 256 μm. The development of CRT, including the median and the 1st and 3rd quartile is illustrated graphically in fig. 3 and 4.

Parametric and non-parametric statistical tests further demonstrated that both the initial values of BCVA and CRT and the values observed observed during the observation period were statistically significantly comparable. In a number of patients we observed statistically significant deviations from the 95% confidence interval in the 6th and 12th month. This concerned patients in whom progression of the pathology occurred (see below).

Effectiveness of treatment and complications

In the period up to 6 months from the beginning of the observation period, stabilisation of the clinical finding was observed in all the patients included in the cohort. In the period between the 6th and 12th month of the observation, progression of the pathology occurred in 5 eyes. Table 4 illustrates the numbers of eyes and an evaluation of the effectiveness of treatment in the individual observation intervals, and the proportion of stabilisation, progression and failure of treatment. The clinical effect of treatment in all eyes during the course of the entire observation period is shown by the graph in fig. 5. Within 12 months of the observation period, no complications were observed.

DISCUSSION

Our study evaluates the results of treatment by laser photocoagulation of the retina with low impulse times and using patterns in eyes of patients with diabetic retinopathy, indicated for panretinal photocoagulation of the retina. In indications of PRP and in the treatment itself we took as our basis the DRS and ETDRS studies, and performed "full scatter PRP" (5). Some authors mention and recommend also other methods of laser photocoagulation of the retina, such as focal treatment, "mild scatter PRP", quadrant treatment in DR, technique of photocoagulation of the supplying blood vessel, bordering of tractional reti-

Fig. 2 Values of BCVA (logMAR) at initial visit and at individual intervals (M – month)

nal detachment and others (10, 18). We intentionally did not use these techniques, since these concern procedures which are not unequivocally supported by studies meeting the most stringent requirements (degree A, I) of evidence based medicine.

From the analysis of BCVA it is possible to judge that stabilisation of BCVA was significant in all the patients in our cohort. Little demonstrated that 75% of patients after PRP maintained visual acuity of 20/100 and better after 5-12 years of observation, and as many as 60% of patients had visual acuity of 20/50 and better (10). In our cohort, 97% of patients retained BCVA of 20/100 and better, and 92% of patients BCVA of 20/50 and better. We recorded a deterioration of visual acuity in patients who at the outset had BCVA on the borderline of 0.3 in units of logMAR. A deterioration of vision by 3 and more rows occurred in 7 eyes (7.7%), in all cases this concerned patients in whom the pathology progressed and vitreous haemorrhage occurred. All this data is comparable with the values observed in the DRS study (21).

Fig. 5 Clinical effect of treatment (N = 91)

In our cohort, stabilisation of the clinical finding was achieved in all the observed eyes in the period of 6 months after the beginning of LPC. In the ETDRS study there was a progression to high risk PDR in eyes in which early full PRP was performed in 5-18% of cases after 3 years, and in 10-30% after 7 years of observation (4). In the DRS study, after 1 year of observation and following the performance of PRP, 78.8% of treated eyes were without neovascularisation (NV). NVD developed in 7.5% (3.8% mild NVD and 3.8% medium or severe NVD). In eyes with mild NVE there was a progression of NV in 22.8% of all treated eyes. In eyes with medium or severe NVE there was a progression in 16.6% of treated eyes. In eyes with mild NVD there was a progression in 19.8% of eyes (21). In long-term assessment, the clinical finding remained stable in 84.6% of patients in our cohort.

One of the fears upon performance of PRP treatment in one session is the quantity of energy supplied to the retina at once during a short treatment time, and the capacity of the retina to sustain this energy while retaining circulatory parameters, primarily within the region of the posterior pole of the retina. We may consider CRT to represent an indirect parameter of these relations. Muqit et al. in their cohort did not observe an increase of CRT after treatment in one session, by contrast this occurred after classic treatment performed in four sessions (12). We consider the

Table 4 Effectiveness of treatment in individual intervals (N – number of eyes; M – month of observation)

cohort	12M	18M	24M	30M	36M	42M	48M	Celkem	Celkem %
n	91	65	47	30	29	3	3	91	100
stabilisation	83	60	47	30	28	3	3	77	84,6
progression	5	1	0	0	1	0	0	7	7,7
failure	3	4	0	0	0	0	0	7	7,7

above data to be comparable with our results. Yamakawa et al. (24) and Danielescu and Chiseliţă (3) reached a similar conclusion. On the contrary, Kim et al. recorded an increase in central retinal thickness 1 month after treatment, which then did not change during the observation period of 1 year (9). In the study by Oho et al., macular edema occurred in 11 eyes out of 129 following the performance of PRP in one session 1 month after the performance of the treatment, whilst 3 months after treatment macular edema spontaneously regressed in 5 of these 11 eyes (17). Nagpal et al. did not identify any change of central retinal thickness in their cohort following laser treatment (13). From the perspective of development of macular thickness after the performed treatments, we consider our results to be comparable with the studies published to date.

The complications that are described in the literature and which may have a correlation with aggressive conventional laser photocoagulation performed in a single session are choroidal ablation, ablation of the ciliary body, exudative retinal detachment or occlusion of the chamber angle. A rare complication observed after PRP performed in two sessions using a Pascal laser is central serous chorioretinopathy (25). Sheth et al. observed 2x retinal haemorrhage and 2x choroidal ablation in 666 PRP treatments performed using a Pascal system (17). Velez-Montoya et al. published data in which they retrospectively evaluated over 1301 laser procedures, in 2 eyes (0.17%) they observed choroidal ablation and in 1 eye (0.07%) serous retinal detachment, both complications corrected themselves spontaneously (23). A further complication they encountered was retinal haemorrhage (17 eyes, 1.3%). This complication was observed also by Modi et al. (11). In our cohort no complications of laser treatment were observed.

In the future we see potential for a comparison of the effectiveness of treatment of innovative types of lasers also with other therapeutic modalities, in particular in combination with anti-VEGF preparations administered intraocularly (14). New experiences demonstrate that the application of anti-VEGF agents separately or in combination with PRP has an unequivocally positive influence on eyes which are resistant or refractive to PRP, in aggressive forms of PDR or in newly diagnosed PDR (2, 20, 22).

CONCLUSIONS

The study presents a complex processing of the issue of laser photocoagulation with the use of technical innovations of lasers in a unique cohort of patients with diabetic retinopathy.

The performance of panretinal laser photocoagulation of the retina with the use of patterns and impulses of fundamentally shorter times during one to two therapeutic episodes in cases of severe advanced NPDR and PDR achieved both stabilisation of BCVA, and in 85% of eyes also stabilisation of the clinical finding. Change of BCVA after this intervention was insignificant during the observation period of 4-12 months. Central retinal thickness was stable during the observation, and no complications were observed.
